

Bugs and what can be done about them...

Bjoern Doebel

Dresden, 2008-01-22

- What are bugs?
- Where do they come from?
- What are the special challenges related to systems software?
- Tour of the developer's armory

- **Error:** some (missing) action in a program's code that makes the program misbehave
- **Fault:** corrupt program state because of an error
- **Failure:** User-visible misbehavior of the program because of a fault
- **Bug:** colloquial, most often means fault

- **Memory/Resource leak** – forget to free a resource after use
- **Dangling pointers** – use pointer after free
- **Buffer overrun** – overwriting a statically allocated buffer
- **Race condition** – multiple threads compete for access to the same resource
- **Deadlock** – applications compete for multiple resources in different order
- **Timing expectations** that don't hold (e.g., because of multithreaded / SMP systems)
- **Transient errors** - errors that may go away without program intervention (e.g., hard disk is full)
- ...

- **Bohrbugs:** bugs that are easy to reproduce
- **Heisenbugs:** bugs that go away when debugging
- **Mandelbugs:** the resulting fault seems chaotic and non-deterministic
- **Schrödingbugs:** bugs with a cause so complex that the developer doesn't fully understand it
- **Aging-bugs:** bugs that manifest only after very long execution times

- Operator errors
 - largest error cause in large-scale systems
 - OS level: expect users to misuse system call
- Hardware failure
 - especially important in systems SW
 - device drivers...
- Software failure
 - Average programmers write average software!

- Software complexity approaching human brain's capacity of understanding.
- Complexity measures:
 - **Source Lines of Code**
 - **Function points**
 - assign “*function point value*” to each function and datastructure of system
 - **Halstead Complexity**
 - count different kinds of operands (variables, constants) and operators (keywords, operators)
 - relate to total number of used operators and operands

- **Cyclomatic Complexity** (McCabe)
 - based on application's control flow graph
 - $M := \text{number of branches in CFG} + 1$
 - minimum of possible control flow paths
 - maximum of necessary test cases to cover all nodes at least once
- **Constructive Cost Model**
 - introduce factors in addition to SLOC
 - number, experience, ... of developers
 - project complexity
 - reliability requirements
 - project schedule

- IDE / debugger integration:
 - no simple compile – run – breakpoint cycle
 - can't just run an OS in a debugger
 - but: HW debugging facilities
 - single-stepping of (machine) instructions
 - HW performance counters
 - stack traces, core dumps
 - printf() debugging
- OS developers lack understanding of underlying HW
- HW developers lack understanding of OS requirements

- Verification
- Static analysis
- Dynamic analysis
- Testing
- Use of
 - careful programming
 - language and runtime environments
 - simulation / emulation / virtualization

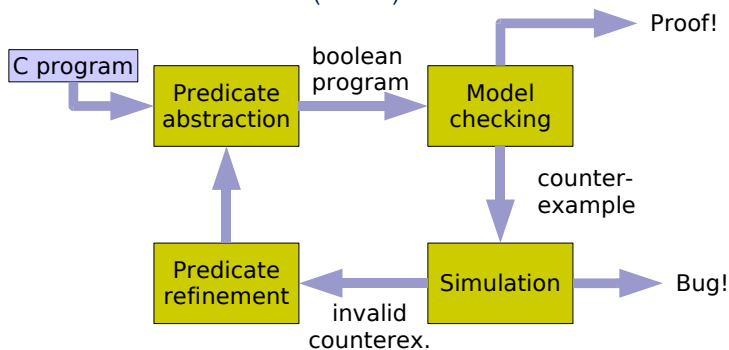

- Goal: provide a mathematical proof that a program suits its specification.
- Model-based approach
 - Generate (mathematical) application model, e.g. state machine
 - Prove that valid start states always lead to valid termination states.
 - Works well for verifying protocols
- **Model checking**

- The good:
 - Active area of research, many tools.
 - In the end you are really, really sure.
- The bad:
 - Often need to generate model manually
 - State space explosion
- The ugly:
 - We check a mathematical model. Who checks code-to-model transformation?

- L4Linux CLI implementation with tamer thread
- After some hours of wget L4Linux got blocked
 - Linux kernel was waiting for message from tamer
 - tamer was ready to receive
- Manually debugging did not lead to success.
- Manually implemented system model in Promela
 - language for the SPIN model checker
 - 2 days for translating C implementation
 - more time for correctly specifying the bug's criteria
 - model checking found the bug

- Modified Promela model
 - tested solution ideas
 - 2 of them were soon shown to be erroneous, too
 - finally found a working solution (checked a tree of depth ~200,000)
- Conclusion
 - 4 OS staff members at least partially involved
 - needed to learn new language, new tool
 - Time-consuming translation phase finally paid off!
 - Additional outcome: runtime checker for bug criteria

- Counterexample Guided Abstraction Refinement
- SATABS toolchain (ETHZ)

- Formal analysis does not (yet?) scale to large-scale systems.
- Many errors can be found faster using informal automated code-parsing tools.
- Approach:
 - Description of how code should behave.
 - Let a parser look at source code and generate description of how the code in fact behaves.
 - Compare both descriptions.

- Trade soundness and completeness of formal methods for scalability and performance.
 - Can lead to
 - **false positives** – find a bug where there is not
 - **false negatives** – find no bug where there is one
- Many commercial and open source tools
 - wide and varying range of features

- 1979
- Mother of quite some static checking tools
 - xmlint
 - htmlint
 - jlint
 - SPLint
 - ...
- Flag use of unsafe constructs in C code
 - e.g.: not checking return value of a function

- Check C programs for use of well-known insecure functions
 - sprintf() instead of snprintf()
 - strcpy() instead of strncpy()
 - ...
- List potential errors by severity
- Provide advice to correct code
- Basically regular expression matching
- **Demo**

- **Source code annotations**
 - Specially formatted comments inside code for giving hints to static checkers
 - `/* @nonnull@ */ int *foo -> "I really know that this pointer is never going to be NULL, so shut the **** up complaining about me not checking it!"`
 - Problem: Someone needs to force programmers to write annotations.
- **List errors by severity**
 - severe errors first

- **Secure Programming Lint**
- Powerful annotation language
- Checks
 - NULL pointer dereferences
 - Buffer overruns
 - Use-before-check errors
 - Use-after-free errors
 - Returning stack references
 - ...
- **Demo**

- Support for program comprehension
 - Doxygen, JavaDoc
 - LXR
 - CScope/KScope
- Data flow analysis
 - Does potentially malicious (tainted) input end up in (untainted) memory locations that trusted code depends on?

- Static analysis cannot know about environmental conditions at runtime
 - need to make conservative assumptions
 - may lead to false positives
- Dynamic analysis approach:
 - Monitor application at runtime
 - Only inspects execution paths that are really used.
- Problems
 - Instrumentation overhead
 - Checking is incomplete

- Can also check timeliness constraints
 - But: take results with care – instrumentation overhead
- How do we instrument applications?
 - Manually
 - L4/Ferret
 - Runtime mechanisms
 - DTrace, Linux Kernel Markers
 - Linux kProbes
 - Binary translation
 - Valgrind

- *Aim*: Runtime monitoring framework for real-time systems with low instrumentation overhead
- Shared-memory ringbuffer for events
 - Instrumented app produces events at low overhead
 - Low-priority monitor collects events without interfering with application execution
- Sensor types
 - Scalar – simple counters
 - Histogram – distributions
 - List – arbitrary events

- Manual instrumentation
 - Dice extension for instrumenting L4 IPC code
 - can make use of Aspect-Oriented Programming
 - can be coupled with other mechanisms, e.g., kProbes

- Linux kProbes
 - Linux kernel modules
 - patch instructions with INT3
 - when hit, debug interrupt occurs
 - inspect (and store) system state before instruction
 - use single-stepping to execute instruction
 - inspect (and restore) system state after instruction
- SystemTap
 - write probes in a scripting language
 - automatically generate kProbe module

- Using traps leads to overhead
- x86 is evil: varying opcode lengths
- Cannot insert arbitrary instrumentation
- DTrace, Linux kernel markers
 - identify interesting locations in the kernel
 - insert bunch of NOOP statements (instrumentation markers), so that there is enough space for inserting instrumentation code
 - write kernel modules to overwrite NOOPs with instrumentation code

- Problems:
 - Lack of source code access for manual instrumentation
 - Lack of knowledge about system internals
 - Markers: need to know interesting instrumentation locations beforehand
- Solutions:
 - Libraries for common instrumentation tasks (Systemtap)
 - Dynamic binary instrumentation (DBI) frameworks

- Annotated binary code (DynamoRIO, Pin)
- Binary-to-binary translation (Valgrind)
 - binary -> intermediate language
 - > instrumented binary

```

0x24F27C:  addl %ebx,%eax
4:  ----- IMark(0x24F27C, 2) -----
5:  PUT(60) = 0x24F27C:I32      # put %eip
6:  t3 = GET:I32(0)            # get %eax
7:  t2 = GET:I32(12)           # get %ebx
8:  t1 = Add32(t3,t2)          # addl
9:  PUT(32) = 0x3:I32          # put eflags val1
10: PUT(36) = t3               # put eflags val2
11: PUT(40) = t2               # put eflags val3
12: PUT(44) = 0x0:I32         # put eflags val4
13: PUT(0) = t1                # put %eax
    
```

- Core
 - Application loader (get rid of dynamic linker)
 - JIT for basic blocks
 - Dedicated signal handling
 - System call wrappers to issue events upon kernel accesses to user memory, registers, ...
- Tool plugins
 - Perform instrumentation on intermediate language
 - replace/wrap certain functions with own implementation

- Aim: provide some function $f()$
- Approach:
 - Write a function `test_f()` testing all possible inputs and error conditions
 - `test_f()` will obviously fail.
 - Now write $f()$ and rerun test case until `test_f()` succeeds.
 - Naturally you get one test for each of your functions.
- Problem:
 - Requires a lot of discipline

- Unit tests
 - test software units (==functions) one at a time
 - external dependencies replaced by stubs (mockups)
- Blackbox testing
 - test for behavior
- Whitebox testing
 - test control flow paths
 - achieve certain code coverage
 - function-, statement-, condition-, path-, exit-coverage

- Good/bad input
- Boundary values
- Random data
- Zero / NULL
- Automation?
 - at least generate test skeletons automatically
 - static analysis can generate test cases
 - special values exist for certain types
 - annotations to define ranges of good input

- xUnit
 - Kent Beck for Smalltalk
 - now available for most major programming languages
- **Test fixture** := predefined state for tests
- **Test suite** := set of tests running in the same fixture
- **assertions** to verify input, output, return values, ...
- available for many programming languages
 - CUnit also available for L4

- Component tests
 - test interaction of several units
- Integration tests
 - test interaction of components
- Regression tests
 - check whether a bugfix introduced problems (regressions) in formerly succeeding tests
- Load/Stress tests
 - test application under heavy load
- Usability tests, user acceptance tests, ...

- Trivia: Is checking return values defensive programming?
- **Design by contract** – functions have
 - Preconditions -> guaranteed by caller
 - Postconditions -> guaranteed by callee
 - Invariants -> guaranteed by both
- Use assertions to check pre- and postconditions
 - overhead?
 - can serve as kind of annotation for static analysis tools

- Virtual machines (QEmu, VMWare, Vbox, ...)
 - simulate HW which otherwise isn't available
 - but: be aware that HW behavior doesn't necessarily match...
- Safe programming languages (Java, C#, ...)
 - builtin garbage collection
 - runtime / compile time type checking
 - not necessarily a bad idea for systems programming:
 - Singularity mostly written in a C# dialect
 - Melange (network stacks in OCaml)
